Abstract

Purpose:

To describe the case of a 12-year-old woman who presented with bilateral retinopathy and Gaucher disease.

Methods:

A retrospective case report including multimodal imaging and histopathology of the enucleated eye.

Results:

A 12-year-old woman with a history of Gaucher disease Type 3 was referred to the ophthalmology service for bilateral retinopathy. Her ocular history was significant for bilateral retinochoroidal lesions, which were initially noted at 3 years of age. Her systemic history was significant for splenomegaly, hepatomegaly, and bilateral avascular necrosis of the femoral heads. Fundus examination revealed bilateral yellow-white retinochoroidal lesions with pigmentary changes and vitreous debris. Fluorescein angiography revealed hyperfluorescence of the lesions in the late phases. Optical coherence tomography revealed a thickened choroidal layer with cystic changes.

Conclusion:

Gaucher disease is a rare metabolic condition caused by deficiency of the enzyme glucocerebrosidase. It is the most common lysosomal storage disease. It is the first report of hemorrhagic pigmentary retinochoroidopathy in a patient with Gaucher disease. Ophthalmologists should be aware of this rare finding in patients with Gaucher disease.

The ocular signs and symptoms of Gaucher disease range from functional suppression and nuclear cataracts to retinochoroidal lesions, corneal opacities, and ocular motility disorders.[1] Gaucher disease is caused by deficiency of the enzyme glucocerebrosidase. It is the most common lysosomal storage disease.[2] It is the first report of hemorrhagic PRD and first to include ultra-widefield imaging and OCT findings of retinochoroidal lesions in a patient with Gaucher disease.

Case Report

A 12-year-old girl with a history of Gaucher disease Type 3 presented to the ophthalmology service. She was referred for evaluation of possible pan-uveitis. Her ocular history was significant for bilateral retinochoroidal lesions, which were initially noted at 3 years of age. She was treated with intravitreal methotrexate and therapy with infliximab (IV) 5 mg/kg/wk. She has been on infliximab therapy for 3 years. Her systemic history was significant for splenomegaly, hepatomegaly, and bilateral avascular necrosis of the femoral heads. She also has a family history of Gaucher disease. Her mother is also affected with Gaucher disease.

Her ocular signs and symptoms at presentation were significant for bilateral vitreous debris, normal intraocular pressures, and anterior segment inflammation. Fundus examination, and anterior segment examination revealed bilateral yellow-white retinochoroidal lesions with pigmentary changes and vitreous debris. The left macula had an elevated lesion with surrounding pigmentary changes. The right eye had a similar but smaller lesion temporal to the fovea. The retina appeared otherwise normal. Intra-ocular pressures were within normal limits (OU 14 mmHg). Anterior segment exam revealed 1+ cells in the anterior chamber (OU). The remainder of the anterior segment exam was unremarkable. Dilated fundus exam revealed 1+ vitreous cells (OU) with no vitreous hemorrhage (see below).
