

Fundus Depigmentation after Immunotherapy for Metastatic Uveal Melanoma

A 72-year-old man presented for follow-up of age-related macular degeneration in the right eye 4 years after enucleation of the left eye for large ciliochoroidal melanoma. He developed metastatic disease treated with systemic pembrolizumab, which was held after 11 doses due to treatment-related myelitis. Fundus examination showed striking depigmentation in the right eye (**B**) compared with fundus photographs at presentation (**A**). OCT showed thinning of the choroid (**D**) compared with presentation (**C**). Visual acuity remained 20/20, and he was asymptomatic without uveitis. He had also developed poliosis and vitiligo. These findings were presumed to be related to his prior immunotherapy. (Magnified version of Fig A–B is available online at www.opthalmologyretina.org/.)
